#### **ABSTRACT**

Context. Open clusters are convenient probes of the structure and history of the Galactic disk. They are also fundamental to stellar evolution studies. The second Gaia data release contains precise astrometry at the sub-milliarcsecond level and homogeneous photometry at the mmag level, that can be used to characterise a large number of clusters over the entire sky.

Aims. In this study we aim to a establish list of members and derive mean parameters, in particular distances, for as many clusters as possible, making use of *Gaia* data alone.

Methods. We compile a list of thousands of known or putative clusters from the literature. We then apply an unsupervised membership assignment code, UPMASK, to the Gaia DR2 data contained within the fields of those clusters.

Results. We obtained a list of members and cluster parameters for 1212 clusters. As expected, the youngest clusters are seen to be tightly distributed near the Galactic plane and to trace the spiral arms of the Milky Way, while older objects are more uniformly distributed, deviate further from the plane, and tend to be located at larger Galactocentric distances. Thanks to the quality of Gaia DR2 astrometry, the fully homogeneous parameters derived in this study are the most precise to date. Furthermore, we report on the serendipitous discovery of 54 new open clusters in the fields analysed during this study.

Key words. open clusters and associations: general Methods: numerical

# 1. Introduction

Our vantage point inside the disk of the Milky Way allows us to see in great detail some of the finer structures present in the solar neighbourhood, but impedes our understanding of the three-dimensional structure of the disk on a larger scale. In order to reconstruct the overall shape of our Galaxy, it is necessary to estimate distances to astronomical objects that we use as tracers, and study their distribution. Since the historical works of Herschel (1785), who estimated photometric distances to field stars, a variety of tracers have been used, such as planetary nebulae, RR Lyrae, Cepheids, OB stars, or HII regions. An abundant literature focuses on clusters as tracers of the Galactic disk.

The stellar clusters belonging to the disk of the Galaxy are traditionally refered to as open clusters (OCs). As simple stellar populations, their ages and distances can be estimated in a relatively simple (albeit model-dependent) way by means of photometry, making them convenient tracers of the structure of the Milky Way (see e.g. Janes & Adler 1982; Dias & Lépine 2005; Piskunov et al. 2006; Moitinho 2010; Buckner & Froebrich 2014). They have been used as such since the study of Trumpler (1930), proving the existence of absorption by the interstellar medium. They are also popular tracers to follow the metallicity gradient of the Milky Way (a non-exhaustive list includes Janes 1979; Friel 1995; Twarog et al. 1997; Yong et al. 2005; Bragaglia & Tosi 2006; Netopil et al. 2016; Casamiquela et al. 2017) and its evolution through time (e.g. Friel et al. 2002; Magrini et al. 2009; Yong et al. 2012; Frinchaboy et al. 2013; Jacobson et al. 2016), providing insight on the formation of the Galactic disk. Studies of the kinematics of OCs and reconstructions of their individual orbits (Wu et al. 2009; Vande Putte et al. 2010; Cantat-Gaudin et al. 2016; Reddy et al. 2016) help us understand the internal processes of heating (Martinez-Medina et al. 2016; Gustafsson et al. 2016; Quillen et al. 2018) and radial migration (Roškar et al. 2008; Minchev 2016; Anders et al. 2017), and how they affect the chemodynamical evolution of the disk. Some very perturbed orbits might also provide evidence for recent merger events and traces of past accretion from outside the Galaxy (Law & Majewski 2010; Cantat-Gaudin et al. 2016).

Open clusters are not only useful tracers of the Milky Way structure but are also interesting targets in their own right. They are homogeneous groups of stars with the same age and same initial chemical composition, formed in a single event from the same gas cloud, and therefore constitute ideal laboratories to study stellar formation and evolution. Although most stars in the Milky Way are observed in isolation, it is believed that most (possibly all) stars form in clustered environments and spend at least a short amount of time gravitationally bound with their siblings (see e.g. Clarke et al. 2000; Lada & Lada 2003; Portegies Zwart et al. 2010), embedded in their progenitor molecular cloud. A majority of such systems will be disrupted in their first few million years of existence, due to mechanisms possibly involving gas loss driven by stellar feedback (Moeckel & Bate 2010; Brinkmann et al. 2017) or encounters with giant molecular clouds (Gieles et al. 2006). Nonetheless, a fraction will survive the embedded phase and remain bound over longer timescales.

Some of the most popular catalogues gathering information on OCs in the Milky Way include the WEBDA database (Mermilliod 1995), and the catalogues of Dias et al. (2002, here-

after DAML) and Kharchenko et al. (2013, hereafter MWSC). The latest recent version of the DAML catalogue lists about 2200 objects, most of them located within 2 kpc of the Sun, while MWSC lists over 3000 objects (including globular clusters), many of which are putative clusters needing confirmation.

Although claims have been made that the sample of known OCs might be complete out to distances of 1.8 kpc (Kharchenko et al. 2013; Joshi et al. 2016; Yen et al. 2018), it is likely that some objects are still left to be found in the solar neighbourhood, in particular old OCs (Piskunov et al. 2018) and sparse nearby OCs with large apparent sizes that do not stand out as significant overdensities in the sky, as the recent discoveries of Röser et al. (2016) and Castro-Ginard et al. (2018) have shown.

The inhomogeneous analysis of the cluster population often lead to discrepant values, due to the use of different data and methods of analysis. This was noted for instance by Dias et al. (2014) and Netopil et al. (2015). Characterising OCs is often done with the use of data of different nature, combining photometry from dedicated observations such as the Bologna Open Clusters Chemical Evolution project (Bragaglia & Tosi 2006), the WIYN Open Cluster Study (Anthony-Twarog et al. 2016) or the Open Cluster Chemical Abundances from Spanish Observatories program (Casamiquela et al. 2016). Other studies make use of data from all-sky surveys (2MASS Skrutskie et al. 2006, is a popular choice for studies inside the Galactic plane), proper motions from the all-sky catalogues Tycho-2 (Høg et al. 2000), PPMXL (Roeser et al. 2010), or UCAC4 (Zacharias et al. 2013), or parallaxes from Hipparcos (ESA 1997; Perryman et al. 1997; van Leeuwen 2007). The study of Sampedro et al. (2017) reports membership for 1876 clusters, based on UCAC4 proper motions alone. The ongoing ESA mission Gaia (Perryman et al. 2001; Gaia Collaboration et al. 2016b) is carrying out an unprecedented astrometric, photometric, and spectroscopic all-sky survey, reducing the need for cross-matching catalogues or compiling complementary data.

Space-based astrometry in all-sky surveys has enabled membership determinations from a full astrometric solution (using proper motions and parallaxes), such as the studies of Robichon et al. (1999) (50 OCs with at least 4 stars, within 500 pc) and van Leeuwen (2009) (20 OCs) using Hipparcos data, or Gaia Collaboration et al. (2017) (19 OCs within 500 pc) using the Tycho-*Gaia* Astrometric Solution (TGAS, Michalik et al. 2015; Gaia Collaboration et al. 2016a). Yen et al. (2018) have determined membership for stars in 24 OCs, adding fainter members, for clusters within 333 pc.

The study of Cantat-Gaudin et al. (2018) established membership for 128 OCs based on the proper motions and parallaxes of TGAS, complementing the TGAS proper motions with UCAC4 data (Zacharias et al. 2013) and 2MASS photometry (Skrutskie et al. 2006). The catalogue of the second Gaia data release (Gaia Collaboration et al. 2018b, hereafter Gaia DR2) reaches a G-band magnitude of 21 (9 magnitudes fainter than TGAS). At its faint end, the Gaia DR2 astrometric precision is comparable with that of TGAS, while for stars brighter than  $G \sim 15$  the precision is about ten times better than in TGAS, allowing us to extend membership determinations to fainter stars and to characterise more distant objects. The Gaia DR2 catalogue also contains magnitudes in the three passbands of the Gaia photometric system G,  $G_{BP}$ ,  $G_{RP}$  (where TGAS only featured G-band magnitudes) with precisions at the mmag level. One of the most precious information provided with Gaia DR2 are individual parallaxes to more than a billion stars, from which distances can be inferred for a large number of clusters.

This paper aims to provide a view of the Milky Way ckuster population by establishing a list of cluster members through the use of *Gaia* DR2 data only. It is organised as follows: Section 2 presents the *Gaia* DR2 data used in this study. Section 3 describes our tools and approach to membership selection. Section 4 presents the individual parameters and distances derived for the detected clusters, and Sect. 5 comments on some specific objects. Section 6 places the clusters in the context of the Galactic disk. Section 7 contains a discussion, and Sect. 8 closing remarks.

# 2. The data

#### 2.1. The multi-dimensional dataset of Gaia DR2

The 1.7-billion-source catalogue of *Gaia* DR2 is unprecedented for an astronomical dataset in terms of its sheer size, highdimensionality, and astrometric precision and accuracy. In particular, it provides a 5-parameter astrometric solution (proper motions in right ascension and declination  $\mu_{\alpha*}$  and  $\mu_{\delta}$  and parallaxes  $\varpi$ ) and magnitudes in three photometric filters (G,  $G_{BP}$ ,  $G_{RP}$ ) for more than 1.3 billion sources (Gaia Collaboration et al. 2018b). The large magnitude range it covers however leads to significant differences in precision between the bright and faint sources. At the bright end (G;14), the nominal uncertainties reach precisions of 0.02 mas in parallax and 0.05 mas yr<sup>-1</sup> in proper motions, while for sources near  $G \sim 21$  the uncertainties reach 2 mas and 5 mas yr<sup>-1</sup>, respectively (see Fig. 1). In this study we only made use of sources brighter than G = 18, corresponding to typical astrometric uncertainties of 0.3 mas yr<sup>-1</sup> in proper motion and 0.15 mas in parallax. In addition to discarding the least informative sources, this cut off value makes our samples smaller and our computations faster, as 80% of the Gaia DR2 sources are fainter than G~18. In terms of distances, this cut corresponds to the magnitude of the turn off stars in a 100 Myr cluster ( $G_{abs} \sim -1.5$ ) seen at 80 kpc, or in a 3 Gyr cluster  $(G_{abs} \sim 3)$  seen at 10 kpc (without considering interstellar extinction). We therefore expect the most distant and oldest known OCs to be near our detection threshold.

**Fig. 1.** Left: parallax nominal error agains G magnitude for a random sample of 10 000 Gaia DR2 stars. Right: distribution of nominal parallax error for the stars brighter than G = 18 (thick histogram) and fainter (thin histogram) of the same random sample.

The *Gaia* astrometric solution is a simultaneous determination of the five parameters  $(\alpha, \delta, \mu_{\alpha*}, \mu_{\delta}, \varpi)$ , and the uncertain-

ties on these five quantities present non-zero correlations, albeit not as strong as in TGAS. The importance of taking correlations into account when considering whether two data points are compatible within their uncertainties is shown in Cantat-Gaudin et al. (2018). The correlation coefficients for a random sample of 10 000 *Gaia* DR2 sources are shown in Fig. 2.

**Fig. 2.** Correlation coefficients between three astrometric parameters for a random sample of 10 000 *Gaia* DR2 sources.

The *Gaia* DR2 data also contains radial velocities for about 7 million stars (mostly brighter than  $G \sim 13$ ), which we did not exploit in this work, but can provide valuable information for a number of OCs.

We queried the data through the ESAC portal<sup>1</sup>, and scripted most queries using the package pygacs<sup>2</sup>.

# 2.2. Choice of OCs to target

We compiled a list of 3328 known clusters and candidates taken from the catalogues of Dias et al. (2002) and Kharchenko et al. (2013), and the publications of Froebrich et al. (2007), Schmeja et al. (2014), Scholz et al. (2015), and Röser et al. (2016). We excluded three well-studied clusters a priori: Collinder 285 (the Ursa Major moving group), Melotte 25 (the Hyades) and Melotte 111 (Coma Ber), because their large extension across the sky makes them difficult to identify. We excluded all the known globular clusters from our list of targets.

Many of the cluster candidates listed in the literature are so-called "infrared clusters". Those were discovered through observations in the near-infrared passbands of the 2MASS survey, observing at wavelengths at which the interstellar medium is more transparent than in optical, and therefore allowing to see further into the Galactic disk. Although *Gaia* is observing at optical wavelengths, its *G*-band limit is 5 mag fainter than the *J*-band completeness limit of 2MASS (in our case 2 mag fainter, since in this study we only use sources with G < 18), which should make most of the clusters detected in the 2MASS data observable by *Gaia* as long as the extinction is lower than  $A_V \sim 5$ .

#### 3. The method

In this workd we applied the membership assignment code UPMASK (Unsupervised Photometric Membership Assignment

in Stellar Clusters, Krone-Martins & Moitinho 2014) on stellar fields centred on each known cluster or candidate.

#### 3.1. UPMASK

The classification scheme of UPMASK is unsupervised, and relies on no physical assumption about stellar clusters, apart from the fact that its member stars must share common properties, and be more tightly distributed on the sky than a random distribution. Although the original implementation of the method was created to stellar, photometric data, the approach was designed to be easily generalized to other quantities or sources, (astronomical and non-astronomical alike, as galaxies or cells). The method was successfully applied to the astrometric data of the Tycho-Gaia Astrometric Solution in Cantat-Gaudin et al. (2018).

We recall here the main steps of the process:

- 1. Small groups of stars are identified in the 3-dimensional astrometric space  $(\mu_{\alpha*}, \mu_{\delta}, \varpi)$  through k-means clustering.
- 2. We assess whether the distribution on the sky of each of these small groups is more concentrated than a random distribution and return a binary "yes" or "no" answer for each group (this is referred to as the "veto" step).

In this implementation we perform the veto step by comparing the total branch length of the minimum spanning tree (see Graham & Hell 1985, for a historical review) connecting the stars with the expected branch length for a random uniform distribution covering the investigated field of view.

To turn the binary yes/no flag into a membership probability, we redraw new values of  $(\mu_{\alpha*}, \mu_{\delta}, \varpi)$  for each source based on its listed value and uncertainty (and the correlations betwen those three parameters), and perform the grouping and the veto steps again. After a certain number of redrawings, the final probability is the frequency with which a given star passes the veto.

# 3.2. Workflow

#### 3.2.1. Finding the signature of the cluster

For every cluster (or candidate cluster) under investigation, we started with a cone search centred on the position listed in the literature. The numbers listed for the apparent size of a cluster can vary significantly from one catalogue to another. The radius used was twice the value Diam listed in DAML, or the value r2 for clusters only listed in MWSC. The size of the field of view is not critical to UPMASK, but a cluster might be missed if the sample only contains the dense inner regions. The contrast between cluster and field stars in astrometric space will not be optimal if the radius used is inappropriately large. In addition, we performed a broad selection in parallax, keeping only stars with  $\varpi$  within 0.5 mas of the parallax expected from their distance (or 0.5 mas around the range of expected parallax, for clusters with discrepant distances in the catalogues). We performed no prior proper motion selection. We ran UPMASK (with 5 redrawings) on each of the investigated fields. Although the procedure of querying the Gaia archive and running the algorithm were fully automated, we inspected and controlled the output of the assignment manually.

#### Where nothing was detected

Where no significant hint of a cluster was found, we performed the procedure again dividing the search radius by two in order to

<sup>1</sup> https://gea.esac.esa.int/archive/

<sup>&</sup>lt;sup>2</sup> https://github.com/Johannes-Sahlmann/pygacs

provide a better contrast between cluster and field stars. For the clusters with expected distances under  $2\,\mathrm{kpc}$ , we inspected the fields one last time working only with stars brighter than G=15, but this final attempt failed to detect any more clusters. The most sparse and nearby clusters (such as Platais 2 or Collinder 65) are usually not detected by our algorithm, and should be investigated with tailored astrometric and photomeric preselection. At the distant end, it is likely that some non-detected clusters have stars in Gaia DR2 that can be identified with an appropriate initial selection, and possibly the use of non-Gaia data. We also failed to find trace of the cluster candidates reported by Schmeja et al. (2014) and Scholz et al. (2015), which are discussed in Sect. 6.

#### Where more than one OC were detected in the same field

In some cases clusters overlap on the sky, leading to multiple detections. Most of the time, such clusters can however be clearly separated in astrometric space or in a colour-magnitude diagram. In those cases (such as the pairs NGC 7245/King 9 or NGC 2451A/NGC 2451B) we manually devised appropriate cuts in proper motion and/or parallax.

#### Where unreported clusters were found

Although this study only aimed at characterising the known OCs and is not optimised for cluster detection, we found dozens of groups with consistent proper motions and parallaxes and a confirmed cluster-like sequence in a colour-magnitude diagram, that to our best knowledge were so far unreported. Those 54 clusters are discussed in Sect. 5.2, and their positions and mean parameters are reported in Table 1.

#### 3.2.2. Running the algorithm on a restricted sample

Once a centroid in  $(\mu_{\alpha*}, \mu_{\delta}, \varpi)$  was identified for all feasible OCs, we only selected stars with proper motions within 2 mas yr<sup>-1</sup> of the identified overdensity, and parallaxes with 0.3 mas. Those values were adopted because they allow to eliminate a large number of non-member stars, while being still larger than the apparent dispersion of the cluster members. For a handful of nearby clusters with large apparent proper motion dispersions (Blanco 1, Mamajek 1, Melotte 20, Melotte 22, NGC 2451A, NGC 2451B, BGC 2632, Platais 3, Platais 8, Platais 9, and Platais 10) we did not restrict the proper motions. In the cases where the clusters present a very compact aspect in proper motion space, we selected sources with proper motions within 0.5 mas yr<sup>-1</sup> of the centroid.

We then ran 10 iterations of UPMASK, in order to obtain membership probabilities from 0 to 100% by increment of 10%. We ended up with a set of 1212 clusters for which at least five stars have a membership probability greater than 50%. Examples are shown in Fig. A.1 to Fig. A.20. The full membership list for all clusters is available as an electronic table.

# 4. Astrometric parameters

#### 4.1. Main cluster parameters

We computed the median  $\mu_{\alpha*}$ ,  $\mu_{\delta}$ , and  $\varpi$  of the probable cluster members (those with probabilities  $\[iensuremath{\wp} 50\%$ ), after removing outliers discrepant from the median value by more than three median absolute deviations. The values are reported in Table 1.

We also report in Table 1 the radius  $r_{50}$  (in degrees) containing 50% of the cluster members. We show this parameter as a function of the mean cluster parallax in Fig. 3. This parameter is not meant to be a physically accurate description of the cluster extension, as the field of view employed for every individual cluster may or may not contain its most external region, and should be taken as an indication of the area in which cluster members are detectable with our method.

It is also well-known that clusters exhibiting mass segregation have significantly different sizes depending on the magnitude of the stars considered (see e.g. Allison et al. 2009; Cantat-Gaudin et al. 2014; Dib et al. 2018). Although the most common approach to estimating the size of an OC is through the fitting of a density profile, other methods have been suggested, such as establishing the radius that provides the best contrast between field and cluster stars in astrometric space (Sánchez et al. 2018). A better estimate of the true extent of a cluster (and identification of its most distant members) could be obtained by modeling the background distribution of the field stars, and considering the individual kinematics of each star, as for instance done by Reino et al. (2018) for the Hyades clusters.

**Fig. 3.** Radius  $r_{50}$  containing 50% of the cluster members identified in this study, against mean parallax of the cluster. The colour code indicates the number of members. The blue, green, and red solid lines indicate the angular sizes corresponding to physical radii of 1 pc, 2 pc, and 5 pc (respectively).

We also report in Table 1 whether the CMD of the clusters present possible red clump stars with membership probabilities greater than 50%. We recall that the membership assignment procedure applied in this study does not rely on any photometric criteria and does not take into account radial velocities. Those potential red clump stars might therefore not all be true members.

#### 4.2. Obtaining distances from parallaxes

We have estimated distances to the clusters through a maximum likelihood procedure, maximising the quantity:

$$\mathcal{L} \propto \prod_{i=1} P(\varpi_i | d, \sigma_{\varpi_i}) = \prod_{i=1} \frac{1}{\sqrt{2\pi\sigma_{\varpi_i}^2}} \exp\left(-\frac{(\varpi_i - \frac{1}{d})^2}{2\sigma_{\varpi_i}^2}\right)$$
(1)

**Table 1.** Summary of mean parameters for the OCs characterised in this study (the full table is available in the electronic version of this paper).

**Notes.** N: number of stars with membership probabilities over 50%. d: mode of the distance likelihood.  $d_+$  and  $d_-$ : modes obtained when adding (respectively subtracting) 0.1 mas to (from) all parallaxes. RC: indicates whether (Y) or not (N) the CMD features red clump stars with membership probabilities greater than 50%.

where  $P(\varpi_i|d,\sigma_{\varpi_i})$  (which is Gaussian and symmetrical in  $\varpi$  but not in d) is the probability of measuring a value of  $\varpi_i$  (in mas) for the parallax of star i, if its true distance is d (in kpc) and its measurement uncertainty is  $\sigma_{\varpi_i}$ . We here neglect correlations between parallax measurements of all stars, and consider the likelihood for the cluster distance to be the product of the individual likelihoods of all its members. This approach also neglects the intrinsic physical depth of a cluster by assuming all its members are at the same distance. This approximation holds true for the distant clusters, whose depth (expressed in mas) is much smaller than the individual parallax uncertainties, but might not be optimal for the most nearby clusters.

As reported in Lindegren et al. (2018) and Arenou et al. (2018) (and confirmed by Riess et al. 2018; Zinn et al. 2018; Stassun & Torres 2018), the *Gaia* DR2 parallaxes are affected by a zero-point offset. Following the guidelines of Lindegren et al. (2018) and Luri et al. (2018), we accounted for this bias by adding +0.029 mas to all parallaxes before performing our distance estimation.

We report in Table 1 the mode of the likelihood, as well as the distances  $d_{16}$  and  $d_{84}$  defining the 68% confidence interval, and  $d_5$  and  $d_{95}$  defining the 90% confidence interval<sup>3</sup>. In addition to the global zero point already mentioned, local systematics possibly reaching 0.1 mas are still present in *Gaia* DR2 parallaxes (Lindegren et al. 2018). To provide a bracketing of the possible distances of the most infortunate cases, we also provide the modes  $d_+$  and  $d_-$  of the likelihoods obtained adding  $\pm 0.1$  mas to the parallaxes.

For the large majority of objects in this study, the assumption that the stars are physically located at the same distance (and therefore have the same true parallax) leads to a small fractional uncertainty  $\sigma_{\langle\varpi\rangle}/\langle\varpi\rangle$  on the mean parallax. Considering that the statistical uncertainty on the mean parallax of a cluster decreases with the square root of the number of stars, 84% of the OCs in our study have fractional errors below 5% (94% have fractional uncertainties below 10%). For those clusters, inverting the mean parallax provides a reasonable estimate of the distance. The presence of a systematic bias however makes the accuracy of the mean parallax much poorer than the statistical precision, and the range of possible distances is better estimated through a maximum likelihood approach. For the most distant clusters, the distance estimate when subtracting 0.1 mas to the parallaxes diverges to infinity. In the presence of this unknown local bias, the distances to clusters with mean parallaxes smaller than ~ 0.2 mas would be better constrained by a Bayesian approach using priors based on an assumed density distribution of the Milky Way (as in e.g. Bailer-Jones et al. 2018) or photometric considerations (e.g. Anderson et al. 2017), or simply with more classical isochrone fitting methods.

#### 4.3. Comparison with the literature

We compared the astrometric parameters obtained in this study with those given in Gaia Collaboration et al. (2018a) for the 38 OCs in common. We find an excellent agreement between the two sets of results, with a typical difference in mean parallax under 0.02 mas, and under 0.05 mas yr<sup>1</sup> in proper motions (see Fig. 4). The largest differences correspond to the most nearby clusters with the largest apparent dispersions in astrometric parameters.

**Fig. 4.** Value of the mean astrometric parameters minus the value quoted in Gaia Collaboration et al. (2018a) for the 38 OCs in common between both studies.

We also made comparisons with the distances to the clusters of the BOCCE project (Bragaglia & Tosi 2006). Figure 5 shows the difference between our parallax determination, and the expected parallax given the literature distance of the cluster. We remark a significant median zero point of -0.048 mas  $(-48 \mu as)$ , slightly more negative than the 0.029 mas value we adopted from (Lindegren et al. 2018). This value is compatible with the independent determinations of Riess et al. (2018), Stassun & Torres (2018), and Riess et al. (2018), who determined zero-points of  $-46 \mu as$ ,  $-82 \mu as$ , and  $-50 \mu as$  respectively. It is also compatible with the values quoted by Arenou et al. (2018) who assessed the zero point with a variety of reference tracers. We however refrain from drawing strong conclusions as to the value of the zero point from the small number of BOCCE clusters, and for the rest of this study we only corrected the parallaxes for the 29  $\mu$ as negative zero point mentioned in Lindegren et al. (2018).

We also attempted a comparison of the distances derived in this study with those listed in the MWSC catalogue. We generally find a good agreement for the clusters with more than a few hundred members, but for most clusters with fewer members the discrepancies can be significant. We remark that the literature values themselves can vary a lot between sources (for instance Berkeley 76 is listed at 2360 pc in MWSC and 12600 pc in DAML), and our distance estimate might be in agreement with both, one, or none of these values, with discrepancies too large to be explained by instrumental errors (e.g. NGC 2509, Fig. 6). We also remark that on average, our distances estimated from parallaxes tend to agree more often with the more distant literature value. We suggest that the isochrone fitting procedure from which most photometric distances are estimated might be biased in many of those instances, as the might be affected by field contamination, as well as the degeneracies between distance, reddening, and metallicity. The strength of the Gaia data does not only reside in parallaxes from which distances can be inferred,

<sup>&</sup>lt;sup>3</sup> The values of  $d_5$ ,  $d_{16}$ ,  $d_{84}$ , and  $d_{95}$  are only reported in the electronic table

**Fig. 5.** Difference between our parallax determination and the expected value given their distance, for the BOCCE clusters. The error bars represent the quadratic sum of our uncertainty and a 5% error on the reference distance. References are listed in Table 2.

and in precise and deep photometry, but also in our ability to obtain clean colour-magnitude diagrams from which astrophysical parameters can be infered.

**Fig. 6.** Sky distribution (top left), colour-magnitude diagram (top right), and parallax as a function of magnitude (bottom) for the members of NGC 2509. The median parallax is 0.36 mas. Available literature distances for this cluster are 912 pc (DAML, blue), 1700pc (MWSC, green) and 2900 pc (Carraro & Costa 2007, red), which correspond to parallaxes of 1.09 mas, 0.59 mas, and 0.35 mas (respectively).

#### 5. Specific remarks on some clusters

It would be lengthy and impractical to devote a section to every object under analysis in this study, but we provide additional comments on the specific cases of two clusters classified as OCs that are likely globular clusters, and on the previously unreported OCs discovered in this study.

# 5.1. BH 140 and FSR 1758 are globular clusters

The colour-magnitude diagrams of BH 140 and FSR 1758 (shown in Fig. 7) present the typical aspect of globular clusters, with a prominent giant branch and an interrupted horizontal branch displaying a gap in the locus occupied by RR Lyrae. They are also clearly seen as rich and regular distributions on the sky. These two objects, located near the Galactic plane (b=-4.3° and

-3.3° for BH 140 and FSR 1758, respectively) also exhibit small parallaxes ( $\varpi$ =0.16 mas and 0.09 mas), so their distances cannot be estimated accurately from parallaxes alone. FSR 1758 however seems to be located close to the Galactic centre, given its longitude  $l=349.2^\circ$ .

The broad appearance of the CMD of BH 140 can be explained by blended photometry in the inner regions. As discussed in Evans et al. (2018) and illustrated in Arenou et al. (2018), the  $G_{BP}$  and  $G_{RP}$  fluxes of Gaia DR2 sources might be overestimated as a result of background contamination, and the effect is especially relevant in crowded fields such as the core of globular clusters.

The bottom panels of Fig. 7 show that their distinct proper motions allow us to separate the cluster members from the field stars, picking 434 probable members out of 13 000 sources in the case of BH 140, and 540 probable members out of more than 120 000 sources in the very populated field of FSR 1758.

**Fig. 7.** Top left: colour-magnitude diagram for BH 140. Middle left: distribution on the sky for the same stars. Bottom left: proper motion diagram showing the field in light grey, and the cluster stars as black dots. Right column: same for FSR 1758.

#### 5.2. Newly found clusters

We report on the serendipitous discovery of 54 hitherto unreported candidate clusters. These clusters, hereafter named "Gulliver", were found investigating the known OCs. They were identified as groups of stars with consistent proper motions and parallaxes, and distributions on the sky significantly more concentrated than a uniform distribution. We also verified that their CMDs present aspects compatible with them being single stellar populations, but did not perform any additional comparisons with stellar isochrones.

All of them were found in the same field of view as a known OC under investigation, but have distinct proper motions and parallaxes and a distinct aspect in a colour-magnitude diagram, therefore are not necessarily related. The location, proper motions, parallaxes and colour-magnitude diagram of Gulliver 1 are shown in Fig. 8, as an example.

**Fig. 8.** Top left: Ruprecht 91 and Gulliver 1 seen as overdensities in a proper motion diagram. Top right: location of the stars selected from their proper motions. Bottom left: parallax against *G* magnitude for those selected stars. Bottom right: CMD of those selected stars. The selection used in this figure was performed on proper motions only for illustration purposes.

The estimated distances of those proposed new clusters range from 415 to 8800 pc, and 32 of them are within 2 kpc of the Sun. They are not located in a specific region of the sky, but rather seem randomly distributed along the Galactic plane. Their coordinates and parameters are listed in in Table 1, and their distribution projected on the Galactic plane in Fig. 9.

#### 5.3. The non-detected clusters

The total number of clusters for which we were able to identify members (1212) is significantly lower than the initial list of clusters and candidates (3328). We recovered the majority of OCs for which MWSC lists expected distances within 1 kpc, and about half those with proposed distances larger than 3 kpc. A lot of the clusters in the intermediate distance range (1 to 2 kpc) lie in regions of high extinction, and might not be detectable with *Gaia* data alone, or at least not with our method which does

not consider photometry nor radial velocities. For instance, we only find clear trace of 110 out of 837 of the OCs of Froebrich et al. (2007) (listed in the catalogues as "FSR") discovered with 2MASS data. We also remark that we did not find trace of any of the 203 candidates of Schmeja et al. (2014) and Scholz et al. (2015), which are discussed in Sect. 6.

# 6. Distribution in the Galaxy

The distances inferred in Sect. 4.2 can be used to place the clusters on the Galactic plane. Their distribution is shown in Fig. 9. We notice that they clearly trace the Perseus arm, the local arm, and the Sagittarius arm of the Milky Way. We remark that the Perseus arm appears interrupted between  $l=135^{\circ}$  and  $l=240^{\circ}$ . Using the cluster ages listed in MWSC as a colour-code visually confirms that the youngest clusters are clearly associated with the spiral arms, while older clusters are distributed in a more dispersed fashion, which is naturally explained by the fact that spiral arms are the locus of star formation (see e.g. Dias & Lépine 2005).

The lack of clusters tracing the Perseus arm is not due to a bias in our method, but to a general lack of known tracers in that direction, especially at the expected distance of the arm.

Figure 10 shows that, as expected, young clusters are found near the plane, while older clusters can be found at all Galactic altitudes (see e.g. Lynga 1982; Bonatto et al. 2006; Buckner & Froebrich 2014, and references therein). It is also apparent that fewer OCs are found at small Galactocentric radii, and that old clusters tend to be found in the outer disk. This observation was already made by Lynga (1982), and is here very obvious from Fig. 10. Given that the ages in literature and in catalogues show discrepant values for many clusters, this will be investigated in future works using *Gaia* data and homogeneous analysis (Vallenari et al., in prep.), as many ages (and in particular those of the clusters where our distances are at odds with MWSC) should be revised.

As the literature lists some candidate clusters in that empty region, we investigated the posibility that our sample might suffer from an observational bias. The 203 OC candidates reported by Schmeja et al. (2014) and Scholz et al. (2015) with proposed ages  $\log t > 8.5$  are located at high Galactic latitudes, most of them towards the inner disk, with expected Galactocentric distances  $R_{\rm GC} \sim 6000\,{\rm pc}$  to  $8000\,{\rm pc}$  and altitudes  $Z\sim400\,{\rm pc}$  to  $800\,{\rm pc}$  (displayed in the bottom panel of Fig. 10). We failed to identify any of those candidates with *Gaia* DR2 data, despite the fact that the majority of them have proposed distances under 2 kpc in direction of low-extinction regions, and suggest that at least a significant fraction of them are not true clusters.

In Figure 11 we display Z and  $R_{GC}$  as a function of age, showing that the median distance from the Galactic plane is about constant for clusters up to  $\log t \sim 8.5$  (44 pc), then increases with age (61 pc for 8.5;  $\log t$ ; 9, 204 pc for  $\log t$ ; 9). The apparent lack of young clusters with Galactocentric distances larger than 10 kpc is due to the incompleteness of the Perseus arm.

# 7. Discussion

Although several authors have claimed (or assumed) that the census of OCs was complete out to distances of 1.8 kpc, the recent discoveries of Castro-Ginard et al. (2018) who found 31 OCs in TGAS data, half of which closer than 500 pc, as well as the serendipitous discoveries reported in this study, open the

question on how many clusters remain to be found within this distance. A dedicated search, possibly combined with non-*Gaia* data such as near-infrared photometry and deep all-sky surveys would no doubt reveal more clusters in the vicinity of the Sun, and extend the cluster discoveries to larger distances. *Gaia* data has also revealed new distant objects at high Galactic latitudes (Koposov et al. 2017; Torrealba et al. 2018), which can be further characterised through dedicated studies.

The main goal of this study is to list cluster members and derive astrometric parameters and distances from Gaia DR2 data alone. The precision and depth of the Gaia photometry coupled with the ability to distinguish cluster members from their astrometry allows to determine reliable cluster ages for an unprecedently large sample of clusters. Accurate fitting of isochrones to photometric data however relies on assumptions on the chemical compositions of the stars under study (most importantly their metallicity and alpha-abundance) and can be much improved when the metallicity is accurately known (see e.g. Randich et al. 2018). The observational campaigns of the Gaia-ESO Survey (Gilmore et al. 2012), APOGEE (Frinchaboy et al. 2013), or GALAH (Martell et al. 2017) have OC stars among their targets, but less than 5% of the currently known OCs have been studied through means of high-resolution spectroscopy. The ambition of deriving cluster ages is beyond the scope of this paper, and will be published in Vallenari et al. (in prep.).

The results presented in Sect. 6 clearly show that old and young clusters present distinct distributions, with old clusters being found further from the Galactic plane. The striking absence of high-altitude clusters with  $R_{\rm GC}$ ;7 kpc could be due to clusters in the dense environment of the inner disk being disrupted before having the time to move to higher orbits. Possible scenarios invoking outwards migration could be tested if reliable metallicity determinations were able to link some of the old, high-altitude OCs to a birthplace in the inner disk.

In addition to the proper motions, *Gaia* DR2 contains radial velocities for 7 million stars, which we did not exploit in this study. Those velocities, complemented with ground-based observations, allow to infer Galactic orbits for a large number of OCs, and understand how the different populations behave kinematically, which is the topic covered by the study of Soubiran et al. (in prep.).

# 8. Summary and conclusion

In this paper we rely on *Gaia* data alone and apply an unsupervised membership assignment procedure to determine lists of cluster members. We provide the membership and mean parameters for a set of 1212 clusters, including 54 newly discovered objects and two globular clusters previously classified as OCs. We derive distances from the *Gaia* DR2 parallaxes, and show the distribution of identified OCs in the Galactic disk. We make use of ages listed in the literature in order to confirm that young and old clusters have significantly different distributions, with young objects following more tightly the spiral arms and plane of symmetry of the Galaxy, while older clusters are found more dispersed and at higher altitudes. They are also rarer in the inner regions of the disk.

Open clusters have been a popular choice of tracers of the properties of the Galactic disk for decades, partly because their distances can be estimated relatively easily by means of photometry. They also constitude valuable targets to study stellar astrophysics. In the *Gaia* era of sub-milliarcsecond astrometry, OCs still constitue valuable tracers, because the mean parallax of a group of stars can be estimated to a greater precision than for

**Fig. 9.** Left: location of the OCs projected on the Galactic plane, using the distances derived in this study. Superimposed is the spiral arms model of Reid et al. (2014). The yellow dots indicate the objects newly identified in this study. Right: same sample of OCs, colour-coded by age (as listed in MWSC).

**Fig. 10.** Top: distance Z to the Galactic plane vs Galactocentric distance, colour-coded by age (as listed in MWSC). The colour scale is the same as in Fig. 9. Bottom: positions of the OCs identified in this study (black dots) and expected location of the candidates of Schmeja et al. (2014) and Scholz et al. (2015), which were not found in this study.

**Fig. 11.** Top: Galactocentric distance (using the distances derived in this study) against age (from MWSC) for all OCs identified in this study. Bottom: distance Z from the plane against MWSC age for the same set of OCs.

need for further observational, methodological and data-analysis studies oriented towards the discovery of new OCs in the most distant regions of the Milky Way.

# **Acknowledgements**

This work has made use of data from the European Space Agency (ESA) mission *Gaia* (www.cosmos.esa.int/gaia), processed by the *Gaia* Data Processing and Analysis Consortium (DPAC, www.cosmos.esa.int/web/gaia/dpac/consortium). Funding for the DPAC has been provided by national institutions, in particular the institutions participating in the *Gaia* Multilateral Agreement. This work was supported by the MINECO (Spanish Ministry of Economy) through grant ESP2016-80079-C2-1-R (MINECO/FEDER, UE) and ESP2014-55996-C2-1-R (MINECO/FEDER, UE) and MDM-2014-0369 of ICCUB (Unidad de Excelencia 'Mara de Maeztu').

The preparation of this work has made extensive use of Topcat (Taylor 2005), and of NASA's Astrophysics Data System Bibliographic Services, as well as the open-source Python packages Astropy (Astropy Collaboration et al. 2013), numpy (Van Der Walt et al. 2011), and scikit-learn (Pedregosa et al. 2011). The figures in this paper were produced with Matplotlib (Hunter 2007) and Healpy, a Python implementation of HEALPix (Górski et al. 2005).
